ANNUAL MEETING - JUNE 1974

Comparative study of the stock distribution of yellowtail (Limanda ferruginea, Storer, 1839) on Nova Scotia and Georges Banks

by

J. P. Berthome ISTPM St. Pierre et Miquelon

Introduction

Meristic and morphometric characteristics of yellowtail were studied in four areas of the Scotian Shelf and in one on Georges Bank from sampling data derived from various cruises to the areas by the R/V Cryos. The study aims at distinguishing between the true groups of the different populations, if differences exist. The following definitions were adopted for the terms group and population:

- two groups are distinct if at least one characteristic (meristic or metric) has a different average value for each of the two samples; that is, if the samples studied belong to two statistical populations for the characteristic or characteristics;
- two populations are distinct if at least three characteristics (meristic or metric) each have a different average value for each of the two samples; that is, the samples studied belong to different statistical populations for each of at least the three characteristics studied.

Materials and Methods

1. Areas studied

The following areas were selected for study partly because of the bathymetric limitations of the yellowtail and partly because the species migrates very little (Fig. 1):

Area 1 : East of Banquereau (Eastern Shoals) Area 2 : North of Sable Island Area 3 : South of Sable Island Area 4 : Sable Island Bank Area 5 : Georges Bank

2. <u>Characters studied</u>

Meristic characters examined are: the number of dorsal fin rays (RD), the number of anal fin rays (RA), and the number of gillrakers on both limbs of the anterior gill arch.

Morphometric characters studied are: ratio of head length (LG^1) to total length (LT), and the ratio of snout length (Ls) to head length (LG^1) :

- where LT = total body length, taken from the anterior extremity of the lower jaw to the medioposterior extremity of the caudal fin;
 - LG¹ = head length, taken from the anterior extremity of the lower jaw to the posterior part part of the cartilagenores edge of the upper gill cover;
 - Ls = snout length taken from the anterior extremity of the lower jaw to the anterior edge of the left eye socket.

3. <u>Statistical methods</u>

1. 1-

The available data were grouped by area (and also sex where necessary) to give a series of frequency distributions for each of the characters studied, and the samples treated statistically using the following parameters:

 $\begin{array}{ll} n & = \text{ number of specimens} \\ M & = \text{ average} \\ \sigma & = \text{ standard deviation} \\ \sigma^2 & = \text{ variance} \\ Sm & = \text{ standard error (standard deviation of the mean)} \\ MISm & = 95\% \text{ confidence limits.} \end{array}$

The means and their 95% confidence limits are recorded graphically for each characteristic and each study area. In this way any differences can be distinguished graphically, or by homogeneity (Lamotte, 1962). This test involves calculating the parameter

$$t = \frac{M_1 - M_2}{c_4} ,$$

where M_1 and M_2 are the means of the two sampled characters being tested, and the standard error of the difference,

$$Sd = \sqrt{Sm_1^2 + Sm_2^2}$$

If t is greater than 1.96, the sample means are significantly different and the samples may be considered to have been taken from two different populations (positive test, +). The t-test is valid if the number of degrees of freedom $(n_1 + n_2 - 2)$ is greater than 30, which is the case for all comparisons made in this study.

Results

The results of the t-tests are given in Table 1, and the frequency distributions and associated parameters for the various characters studied are given in Tables 2-7.

1. Dorsal fin rays (RD) (Table 1, 2; Fig. 2A)

Since no significant sexual dimorphism exists for this character, the area comparisons are based on the total number of individuals in the samples. Fig. 2A shows a very low average for area 5, and test 4-5 (Table 1) indicates that the samples were drawn from two different populations. The samples from area 1, 2, 3 and 4 are not distinctly different. Thus the yellowtail in area 5 may be considered to be distinctly different from those in the other areas which belong to the same population.

2. Anal fin rays (RA) (Table 1, 3; Fig. 2B)

As for dorsal fin rays, there is no significant sexual dimorphism for anal fin rays (Scott. 1954). The average recorded for area 5 (Georges Bank) is slightly higher than that obtained by Lux (1963). Fig. 2B shows a lower average for area 5 than for the other four areas. Since tests 1-2 and 2-5 (Table 1' are positive, the area 5 sample is different from the others. Furthermore, the fish in areas 1 and 4 do not belong to the same population.

3. Gillrakers (Table 1, 4; Fig. 2C)

Again there is no significant sexual dimorphism in gillraker counts and the areas are compared on the basis of the sexes combined. Fig. 2C shows a lower average for area 5, but the other areas do not have a common population as indicated by test 4-1. It seems that there are two populations: one in area 5 and the other consisting of two groups, areas 1 + 2 and areas 3 + 4.

4. <u>Head length to total length ratio</u> $\left(\frac{LG^1}{LT} \times 10^2\right)$ (Table 1, 6; Fig. 2D)

There is significant sexual dimorphism for each area for this character (Table 5, Fig. 3). For fish of equal length, females have a longer head than males. Although the ratio of males to females in the samples differ somewhat from area to area, comparisons by area for sexes combined give the same conclusions as comparisons by area for sexes separate. The samples from area 5 again differ from the others. In summary, we have two populations: one in area 5, and the other consisting of two groups, areas 1 + 2 and areas 3 + 4.

5. <u>Shout length to head length ratio</u> $\left(\frac{\text{Ls}}{\text{LG}^1} \times 10^2\right)$ (Table 1, 7; Fig. 2E)

For this character, the Ls : LG¹ ratio for males and females have the same value, when fish of the same length are compared. Since the head length of the female is greater than that of the male, the snout length is therefore also greater in the female. This character gives a greater difference in the averages for the various areas (Fig. 2E). It is distinctive in all areas, except between areas 1 and 4, where the RA character is distinctive. In summary, there are three populations: area 5 being one, groups 1 and 2 forming the second, and groups 3 and 4 forming the third.

Discussion and Conclusions

Two remarks can be made: (a) if the meristic characteristics do not vary during the adult life, they do not stabilize until the larva goeasto the bottom (Bigelow and Schroeder, 1953); (b) the metric characteristics vary with age, however the year-class distribution was comparable in the areas studied, except in area 5.

Generally, the meristic characteristics do not show significant sexual dimorphism. The metric characteristics on the other hand, have this feature. When males and females are of equal length, the females have a longer snout nad head than the males.

From this study, we have found three distinct populations of yellowtail flounder. The first is found on Georges Bank, and the other two, off the narrows of Sable Island. The latter two are each formed of two groups (Table 8). They are both completely separate from the Georges Bank population. They are separated bathymetrically by the narrows of Sable Island, but certainly undergo interactions due to their geographic proximity.

Table 8 - Populations and groups distinguished in this study.

Populations	: Groups :
Georges Bank (zone 5)	:
North Gully population	: East Banquereau (zone 1) : : North of Sable Island Gully (zone 2)
South Gully population	: : South of Sable Island Gully (zone 3) : : Sable Island Bank (zone 4) :

Fig. 1. Map showing zones studied.

- 9 -

Fig. 2. Averages and their validity amplitudes for each character and each zone (sex mixed).

A = Number of dorsal fin rays : RD B = Number of anal fin rays : RA C = Number of gillrakers D = Ratio: $\frac{LG^1}{LT} \times 10^2$ E = Ratio: $\frac{Ls}{LG1} \times 10^2$

amplitudes, by sex, for the ratio: $\frac{LG^{1}}{LT} \times 10^{2} \text{ (for each zone).}$
