SCIENTIFIC COUNCIL MEETING - JUNE 1985

Status of the Scotian Shelf Silver Hake Population in 1984

by

D. E. Waldron and L. P. Fanning

Marine Fish Division, Dept. of Fisheries and Oceans
P. O. Box 1006, Dartmouth, Nova Scotia, Canada B2Y 4A2

INTRODUCTION

The Scotian Shelf silver hake fishery was once conducted over the total shelf. Evaluation of this fishery, in particular its compatibility with the International Commission for the Northwest Atlantic Fisheries (ICNAF) objectives of maximizing silver hake catches while minimizing by-catches, resulted in the establishment of the present day Small Mesh Gear Line (SMGL). This line loosely follows the 100 meter contour along the Scotian Shelf slope.

Several papers have been written evaluating the placement of the SMGL and its impact upon the silver hake fishery. Waldron & Sinclair (1984) summarized these and presented new analyses of a 1977-1979 joint Canada-Cuba-USSR research program on commercial vessels permitted to fish landward of the SMGL and subsequent observations of the SMGL fishery to 1983. These new analyses agreed with the original management objectives for the placement of the SMGL. The silver hake fishery commenced April 15 and continued until September each year. Catches along the shelf slope (ie seaward of the SMGL) were higher than those occurring landward of the SMGL. From 1977-1979, silver hake catches occurred along the slopes of Emerald and LaHave Basins beginning in June with peak catches in July. Although fairly good catches occurred these were not as great as those seaward of the SMGL. By September, the fishery along the slope was greatly reduced due to low catches. However, catches in the vicinity of Emerald Basin and further inshore were higher than those occurring seaward of the SMGL.

The above study showed a fishing pattern for silver hake predominately along the Scotian Shelf slope from April until June. In July fisheries were conducted predominately along the slope with a smaller fishery in the vicinity of Emerald and LaHave Basins. These results agree well with earlier work by Clay (1979) who compiled, from Soviet fishing reports, a spatial description of the silver hake fishery between 1961 and 1968. From January to March fishing occurred in areas landward of the present day SMGL. From April to June, the USSR fished for silver hake exclusively in areas seaward of the SMGL. During July and August 39 % of the catch was from areas landward of the SMGL. As the fishing season progressed more of the catch was reported in areas landward of the SMGL but fishing still occurred seaward of the SMGL. Monthly catches from the Soviet fishing atlas for 1961-1968 showed that approximately 70 % of the silver hake catch for the 1961-1968 period occurred between April and July in areas which were seaward of the present day SMGL.

Data as detailed as those above are not available for the 1969-1976 period. However, it is unlikely that the fishing pattern for 1969-1976 would not be substantially different from those reported for 1961-1968. Data presented by Waldron and Sinclair (1984) for the 1977-1983 also agrees with the 1961-1968 fishing pattern.

CATCH AND EFFORT

There has been a steady decrease in silver hake catches since 1970 except in 1973 when the highest catches were reported (Figure 1). Nominal catches since 1977 fluctuated between 33 and 60 thousand tons until 1984 when 74 thousand tons of silver hake were caught (Table 1). The decreasing trend in catches are in part due to the implementation of the SMGL management policy in 1977. The major participants in the fishery have been the Soviet Union and recently Cuba, although the USSR continues to have the major portion of the TAC (Table 2 and Figure 2).

A more realistic method of evaluating the post 1976 catches would be to evaluate catch success against the amount of silver hake allocated. Percent caught of the total allocations for non-Canadian fleets have fluctuated between 64 and 90%. The highest years are 1982 (60,000 t) and 1984 (74,000 t).

Waldron (1983) reported that the high catches of 1982 were the result of lower than normal water temperatures on the Scotian Shelf during the months of May and June. This cannot be said of 1984 when water temperatures during the peak period of the fishery showed no obvious anomalies compared to the 1970-1980 average (R. Trites, pers. comm.). The high catches in 1984 may be indicative of increased population size.

The 1984 fishery unlike that in 1983 remained strong until September and most of the allocations were taken. Monthly catches in 1984 were highest in July with 26 thousand tons (35%) caught (Table below). Catches in April to June accounted for 59% of the total yearly landings.

A multiplicative model (Gavaris, 1980) for the 1970 to 1983 catch and effort series was not run for this assessment. Using this model, Waldron and Harris (1984) presented a catch and effort time series standardized to June 1970 for Soviet tonnage class 7 vessels. Standard errors were such that most of the standardized mean catch rates overlapped each other, except the 1982 point which may have been an anomalous year as discussed above. Prior to 1977, catch and effort data for the USSR is confounded because all 4uvwx silver hake is reported from mixed fisheries. Certain assumptions were necessary in order to interpret these catch and effort data. Since 1977, the catch and effort series can be interpreted for directed and mixed fisheries using IOP and DFO data sets. Also, the fishery is limited to a season which is 4-6 months in duration. There are no changes to the mesh size fished nor the vessels used in this fishery since 1977. Therefore, the need to employ the Gavaris model on catch and effort data since 1977 is not necessary for this stock.

Catch and effort for 1977 to 1983 are from NAFO Statistical Bulletins (Table 3). To date, effort data for the 1984 fishery have not been reported to the Northwest Atlantic Fisheries Organization (NAFO). The 1984 effort figures below are calculated from catch and effort observed aboard the small-meshed fishery by the Canadian International Observer Program (IOP).

MONTHS	APRIL	MAY	JUNE	JULY	AUG.	SEPT.	OCT.	Tot.
Observed (t)	1952	8961	8959	7962	1806	196	1	29843

Calculated hrs.	851	5433	9979	10717	1490	511	-	29016

SAMPLING INTENSITY 1984

Sampling for length and age was from the IOP. From the 74 thousand tons 30 thousand tons (40%) were observed. More than 200 thousand lengths and 1000 otoliths were taken from the catch (Table 4). Coverage levels for this and previous years were above the NAFO standard. Otoliths were aged using the ICNAF standards (Anon. 1977) by Mr. J. Hunt of the Canadian Department of Fisheries and Oceans, St. Andrews Laboratory, St. Andrews, New Brunswick.

CATCH AT AGE

The catch-at-age matrix used in this assessment is presented in Tables 5 and 6. The matrix was calculated in the following manner. For 1984, length frequencies of silver hake collected during the small-meshed fishery were aggregated to produce a single monthly length frequency. These monthly length frequencies were weighted to the 1984 monthly catch (Table 3) using monthly weight-length relationships ($wt=aL^b$) (Table 7). The monthly weight-length relationships were based on individual silver hake lengths and weights measured at sea during the 1984 small-meshed silver hake fishery. The weighted monthly length frequencies were multiplied by monthly age-length keys to produce monthly catch numbers at age. These monthly vectors were summed to give final catch numbers at age for the year.

The catch numbers at age for 1972 to 1979 were prepared by Clay and Beanlands (1980), using age-length keys collected from Canadian July groundfish surveys. Silver hake length frequencies reported to ICNAF were adjusted to catch using weight-length relationships from the Canadian July groundfish surveys. These weighted length frequencies were applied to the Canadian age-length keys to give yearly catch numbers at age. The catch numbers at age for 1970 and 1971 were calculated as above but used an aggregated age-length key from the Canadian July groundfish surveys from 1972 to 1976. Catch numbers at age for 1977 to 1979 used length frequencies collected on board the small-meshed fleets by the IOP and weight-length relationships from the Canadian July groundfish surveys.

Catch numbers at age for 1980 to 1983 (Waldron and Harris, 1984) used length frequencies and weight-length relationships collected on board the small-meshed fleets by the IOP. As in previous years, these were weighted to catch and used to construct the final catch numbers at age. Research vessel weights at length were not used as weights collected by the IOP were more representative of the weights at length during the fishery.

The catch-at-age matrix (Table 5) and percent catch at age (Table 6) indicates that the 1983 year class at age 1 is the largest since the 1975 year class at age 1. The 1980 and 1981 year classes in 1984 are the largest in the series at ages 3 and 4. The 1984 fishery is supported by these three large year classes. The 1985 fishery will be supported mostly by the 1983 year class and only moderately by the 1981 year class. Usually 80 % of the catch is from ages 1 to 4, therefore the 1980 year class will give little support to the 1985 fishery. The 1986 fishery will be almost solely supported by the 1983 year class.

MEAN WEIGHT AT AGE

Weight-length relationships from the Canadian July groundfish surveys (1970-1979) and the IOP (1980-1984) were used to calculate the mean weights at age presented in Table 8. Waldron and Harris (1984) noted that fish older than age 5 weighted, on average, less after 1976 than before 1977. Silver hake less than 5 years old showed no such pattern. The implication of this is that the stock is increasing in abundance, probably due in part to the change in management since 1977.

There is reasonable agreement between the catch biomass and the reported catch per year as shown below.

YEAR	1977	1978	1979	1980	1981	1982	1983	1984
CATCH (T)	37095	48404	51751	44525	42927	60251	35839	74280
BIOMASS(T)	36838	47581	51179	44663	41030	59883	35189	74207

RESEARCH VESSEL INDICES

Adult Surveys

Because of changes in availability due to Canadian regulations since 1977 attempts have been made recently to calibrate VPA's using RV surveys. The usefulness of the RV surveys for this purpose is reduced by annual survey effects which make it very difficult to follow year classes by numbers (Tables 9 and 10).

Two series of surveys are available at present. The major series is the July stratified random groundfish survey conducted since 1970. Although the series is continuous there have been three vessels used over the years. From 1970 to 1981 the A.T.Cameron, using a Yankee 36 trawl, carried out the survey. The survey vessel in 1982 was the Lady Hammond and in 1983 and 1984 the Alfred Needler. Both of these latter vessels use a Western IIA survey trawl. The secondary series is the March stratified random groundfish survey conducted from 1979 to 1984 by the Lady Hammond.

The change in July survey vessels and trawls after 1981 was expected to cause a change in the survey abundance indices. To prepare for the change in vessels a series of comparative fishing experiments was conducted to calibrate the various sections of the series conducted by different vessels.

Analysis of the comparative fishing experiments (Fanning, 1985) resulted in a conversion factor of A.T.Cameron to Lady Hammond or Alfred Needler of 2.3 i.e. catches by the A.T.Cameron are multiplied by 2.3 to calibrate them to more recent catches by the other two vessels. Conversion of the historical survey data allows present and future survey results to be added directly to the existing series.

The abundances at age calculated from the July surveys are given in Table 9 and total abundance is plotted in Figure 3. The abundances at age calculated from March surveys are given in Table 11 and total abundance in March is given in Figure 4.

Examination of each age group as percentages indicates that the 1981, 82 and 83 year classes are all stronger than any since 1977. Age groups 1 to 4 account for approximately 90% of the population abundance on average with ages 1 to 3 accounting for 75 to 80%. In numbers the 1983 year class is the largest seen at age 1 followed by 1981 and 1972.

In Figure 5 it is apparent that the 1973, 1977 and 1979 July surveys caught more silver hake at almost all ages than did the adjacent years in each case. This indicates an inter-annual survey effect which influences all ages similarly. However, it does appear certain that, regardless of how imprecisely, both surveys indicate a high abundance level since 1982. Although the 1983 July survey (Figure 3) shows a sharp drop in abundance from 1982, the March survey (Figure 4) indicates only a negligible drop in abundance in 1983. The March survey does not indicate as large an increase in 1984 as the July survey.

Overall the surveys have shown a strong upward trend in the last 6 years which may have levelled off in the last 2 years.

Juvenile Surveys

Since 1979, the USSR and Canada have been conducting joint surveys for Scotian Shelf juvenile silver hake. Initially the gear used was a Soviet designed juvenile bottom trawl. Although it fished well, there was some doubt as to its ability to sample the total

juvenile population. Juvenile silver hake were found to be high in the water column at night and perhaps below the trawl during the day (Koeller, 1979). More probably, these juveniles were above the Soviet bottom survey trawl. In support of this contention, Fanning (1984) suggests that silver hake of age 1 are probably above the research gear used in the Canadian groundfish surveys. Since 1981 the 24 hour cruise design was replaced by a 12 hour night-time cruise using the International Young Gadoid Trawl (IGYPT) used by member countries of the International Council for the Exploration of the Sea (Koeller et al, 1984).

The juvenile silver hake survey is of a random stratified design similar to that reported by Halliday (1971) for the Canadian Scotian Shelf July groundfish surveys. Koeller et al. (1984) identified a "core" area (strata 60-78,) to survey determined from those locations where most of the silver hake juveniles were caught in both the joint USSR-Canada and Canadian Scotian Shelf ichthyoplankton Program surveys.

During the 1984 NAFO meeting of the Scientific Council questions concerning this assumption were raised. The 1984 survey conducted at the usual time, October-November, addressed this issue. It confirmed Koeller's concept of a core survey area as the area where the majority of silver hake juveniles were caught (Neilson, pers. com.).

The survey results presented in Koeller et al (1984) were recalculated by Dr. John Neilson of the DFO St. Andrews Laboratory in New Brunswick. Below are those re-calculations.

Years	1978	1979	1980	1981	1982	1983	1984
Strat. mean catch/tow	241.47	56.01	26.64	562.73	8.26	248.79	43.85
Unstr. mean catch/tow	166.43	180.40	26.98	603.39	6.92	227.70	43.28

Only the series from 1981 to 1984, using the IGYPT gear will be used as an index of juvenile silver hake abundance. The series indicates that the 1981 and 1983 year classes are large relative to the 1982 and 1984 year classes. This observation agrees well with that seen in the Canadian July groundfish surveys.

PARTIAL RECRUITMENT

Partial recruitment presented in last years assessment was calculated by running one VPA at terminal $F = .25$ and averaging each age over the years 1977-1982. The age of full recruitment was determined as age 3 after examination of the F 's at age in each year (Waldron and Harris, 1984). Fishing mortalities at age for silver hake older than 3 were variable, some larger others smaller than the F 's at age 3. Because of this variability, all F 's at ages 3 and older were set to a partial recruitment of 1.000. This partial recruitment pattern is in agreement with previous assessments. Selectivity experiments reported by Clay (1979) indicated that the expected age of full recruitment of a silver hake fishery, using 60 mm codends, would be at age 3. There has been no change in the codend mesh size for the 4wx silver hake fishery since 1977 and there is no reason to expect a significant change in the partial recruitment pattern since then.

The partial recruitment pattern and F 's at age 9 presented in last years assessment were used in a VPA at a terminal F of 0.25. A flat topped partial recruitment pattern was expected so final F 's at the oldest age were calculated by averaging fishing mortalities over the ages 3-8 and iterating until the difference between consecutive iterations was less than 0.0001. Examination of the F matrix suggested that full recruitment occurred between 3 and 4 years of age. The F matrix since 1977 was normalized to the F at age 3 in each year. Although, 1977 indicated dome shaped partial recruitment,

the remainder of the normalized F matrix indicated that F's in most instances continued to increase beyond age 3. This cannot be explained. The final F's at age were averaged across ages for 1977-1983 and are reported below as "1984 Iteration". For the purposes of this assessment, as in other assessments, all F's for silver hake older than age 3 were set to 1.000. The final 1984 partial recruitment at age is not significantly different than that presented in previous assessments.

Table of Partial Recruitment Patterns

AGE	1	2	3	4	5	6	7	8	9
1979 Assess.	0.150	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000
1980-81 Assess.	0.044	0.444	1.000	1.000	1.000	1.000	1.000	1.000	1.000
1982 Assess.	0.030	0.250	1.000	1.000	1.000	1.000	1.000	1.000	1.000
1983 Assess.	0.041	0.330	1.000	1.000	1.000	1.000	1.000	1.000	1.000
1984 Iteration	0.035	0.350	1.000	1.000	1.000	1.000	1.000	1.000	1.000

NATURAL MORTALITY

Natural mortality for silver hake has been set at 0.400 since sequential population analysis has been used to assess this stock. This estimate is based upon work by Mari and Terri (1979). There is no new data which will permit the re-calculation of this parameter and M = 0.400 will be used in this assessment.

VIRTUAL POPULATION ANALYSIS and CALIBRATION

A virtual population analysis (Gulland, 1965) was used in an attempt to estimate the population size of silver hake in 1984. The input parameters were M = 0.400, the partial recruitment pattern developed above and terminal F's ranging from 0.100 to 0.900. For each terminal fishing mortality, F's were averaged over ages 3-7 until the difference for F's on the oldest age between consecutive VPA's was less than 0.001.

Several attempts were made to calibrate these population estimates. One method was to compare 3+ research vessel numbers and against 3+ mid year VPA numbers. Mid year population numbers were defined as the average numbers at age in Ricker (1975, page 12).

$$\text{Average } N = \frac{N(1-e^{-Z})}{Z}$$

An example of a run at a terminal F at 0.250 are given in Tables 12a,b and 13b and Figure 6.

Another calibration technique is to compare fishable research vessel biomass against fishable VPA biomass. Fishable biomass (FB) is determined as per the following;

$$FB = \text{Mid year POP} \times (\text{Average Normalized F at age [1970-1976 & 1977-1983]})$$

where

$$\text{Normalized F} = [F/\text{Weighted F}] / \text{Max [F/Weighted F]}$$

and

$$\text{Weighted F} = F[\text{ages 3-7}] \times \text{Pop[ages 3-7]} / \text{Sum of Pop[ages 3 - 7]}$$

where F and POP are the F 's at age and population numbers at age at the specified terminal F .

All normalized F 's larger than 1.000 were set to 1.000. These were averaged at each age for 1970-1976 and 1977-1983. The averages at age for 1970-1976 and 1977-1983 were used as partial F 's for the pre extended jurisdiction (1970-1976) and the post 1976 fisheries respectively.

An example of a run at a terminal F at 0.250 is given in Tables 12a-d, and 13a and Figure 7.

Attempts to calibrate the VPA using research vessel surveys were unsuccessful. The 1982-1984 data points are much larger than any in the series since 1977 and as a result the linear relationships are solely dependent upon the magnitude of these points in the above relationships.

Since the NAFO Scientific Council dismissed the use of the CPUE series as it was subject to bias due to the post 1977 management strategy, no attempts to calibrate the VPA with CPUE were made.

YIELD PER RECRUIT AND AVERAGE WEIGHTS AT AGE

A yield per recruit analysis using the Thompson and Bell yield model (Ricker, 1975 and Rivard, 1982) was conducted to evaluate where current average weights for the fishery were in relationship to the $F_{0.1}$ and F_{max} mean weights. The parameters used in the model were $M = 0.400$ and the averaged partial recruitment (1977-1983) and the average mean weights at age for the period 1977-1984. These were selected because the affects of the shift in management in 1977 would begin to be seen in the fishery (Table 14). This was repeated for the 1970-1976 period using average partial recruitments for 1970-1976 and mean weights at age for 1970-1976 (Table 15). Plotting average weights from the catch and at $F_{0.1}$ and F_{max} suggest that fishing since 1976 has been at F 's below $F_{0.1}$ while prior to 1977 fishing was between $F_{0.1}$ and F_{max} (Fig. 8).

CONCLUSIONS

The 1984 fishery is supported by two large year classes (1981 and 1983) as suggested both by the research vessel and juvenile research surveys. These year classes will be in the fishery for 1985 but only one, the apparently strong 1983 year class will contribute significantly to the 1986 fishery. There is no confirmation to date of the size of the 1984 year class seen as weak in the 1984 juvenile survey. Mean weights at age for the 1980-1984 period suggest that the fishery is being conducted below $F_{0.1}$. There is some suggestion that the 1986 fishery would have an $F_{0.1}$ level below that calculated in Table 14. However, there is data to suggest the 1986 fishery will only be supported by one strong year class. The 1985 year class will not be assessed until November, 1985. There is no method to predict its relative size at this time. There is little change in the current calculation of $F_{0.1}$ as compared to that in previous assessments and it is suggested that at this time there is no reason to change the current TAC of 100,000 tons.

ACKNOWLEDGMENT

The authors wish to thank the men and women of the IDP and Marine Fish Division who worked so hard to collect the data used throughout this document. Also, we wish to acknowledge the ageing of silver hake by Mr. Joe Hunt and the analysis of the Juvenile Survey data by Dr. John Neilson, both of the St. Andrews' Biological Station. Special thanks to Mr. R.N. O'Boyle who worked diligently attempting to calibrate the VPA using several other techniques not mentioned in the text above. All, unfortunately, to no avail! Thanks goes to Mrs. Cynthia Harris and Mrs. M. MacIsaac who assisted in the preparation of this document.
