SCIENTIFIC COUNCIL MEETING - JUNE 1989

Results from Bottom-trawl Survey of Flemish Cap in July 1988

by

A. Vazquez

Instituto de Investigaciones Marinas  
Muelle de Bouzas, Vigo, Spain

A fishing survey of Flemish Cap was carried out in July 1988 on board the Spanish R/V CORNIDE DE SAAVEDRA to estimate cod stock abundance, primarily, and also redfish and American plaice. The survey had a bottom trawl stratified random design following NAFO specifications (Doubleday, 1981). A total of 120 bottom trawls were made up to a depth of 720 meters (400 f.). A synoptic sheet of the survey with ship, and gear characteristics is presented in Table 1.

July was chosen as the appropriate month for the survey for two reasons: First, because summer is feeding season for cod and American plaice and presumably populations are dispersed. Secondly, because of good weather in July, necessary to achieve the proposed objectives.

As a additional foresight of bad weather conditions that would prevent complete sampling of all strata, the planned 120 tows were split in two groups of 80 and 40 tows. The sampling scheme was designed to cover the bank with 80 tows in the first group. After completion of this initial coverage of the area, the remaining 40 tows of the second group were made to complete the 120 tows design.

We note that the objective of maintain towing speed at 3.5 noots was not always achieved. Catch per nautical mile trawling data exhibit a smaller variance than catches per tow. We include both result for main species.

Gear used was the one named "Lofoten" and used by R/V CRYOS in bottom survey in NAFO area (Anon. 1986). The gear is quite similar in shape and size to that used in Spanish commercial ships in Flemish Cap because it is adequate to rough bottom. Foogear was equipped with 35 cm bobbins as used in commercial fishery. The use of a 35 mm liner in the codend allowed the catch of cod from 120 mm efficiently.

RESULTS

A complete list of species occurrence is presented in Table 2. Pelagic species included should be caught when gear goes through the water column and their presence are not considered to correspond to their abundance.

Cod

Mean catch by strata and whole bank data and its standard

error are presented in Table 3. Main error in bottom trawl abundance estimation arrives from gear efficiency. Our trawl gear had 3.2 meters of vertical opening according to technical specifications and cod shoals moves off the bottom more than that distance. Based on the 1987 USSR acoustic and bottom trawl survey on Flemish Cap, the ratio of cod abundance near bottom and off the bottom was estimated to be 12.3/9.1 (Bozovkov et al. 1988). This means that 43 per cent of cod biomass should be inaccessible to bottom gears. It was not possible in our survey to calculate this rate.

Another source of gear inefficiency for small fish in particular was the use of footrope bobins, but its use was necessary because of rough bottom on the bank.

It is our objective to repeat this survey in following years to set a annual series of abundance indices that can be considered independent from efficiency and accessibility conditions. But, in spite of these problems, based on sweep area method minimum exploitable biomass estimate was calculated:

|                                |                     |
|--------------------------------|---------------------|
| Bank area .....                | 10,555 sq. n. miles |
| Wing spread .....              | 13.5 m              |
| Area sweep per mile towed .... | 0.0075 sq. n. miles |
| Mean catch per mile .....      | 26.06 Kg            |
| Sweep area estimate .....      | 36,675 t            |

Tables 4, 5 and 6 show length frequency, age length key and age composition of the catch respectively.

#### American plaice

Mean catch by strata and whole bank data and its standard error are presented in Table 7. It was observed that American plaice was distributed in areas with depth less than 360 meters (200 f.), roughly the same area that cod.

Biomass estimated by sweep area method was 11,878 t., but, due to the reduced catchability for flatfishes due to the use of a gear with bobins on the footrope, this result underestimate total stock biomass in a unknown but presumable high degree.

Tables 8, 9 and 10 show length frequency, age length key and age composition of the catch respectively.

#### Redfishes

Redfishes catches were splitted into Sebaste marinus and Sebastes spp.. Scales were used for age determination of S. marinus following the technic described by Kosswig (1980).

Mean catch by strata and whole bank data and its standard error are presented in Table 11.

Biomass estimates by sweep area method were 15,467 t. and 155,032 t. for S. marinus and Sebastes spp. respectively. In the USSR survey previously mentioned (Bozovkov et al. 1988), the observed ratio between redfish biomass in the zone adjacent to the bottom and that off the bottom was 106.4/350.0. That means that 77 per cent of redfish biomass were inaccessible to bottom trawl gears.

Tables 12, 13 and 14 show length frequency, age length key and age composition of the catch respectively.

Shrimp (*Pandalus borealis*)

Shrimp catches reached 50 Kg in half hour. This indicates the occurrence of important concentrations of this species. In Table 15 mean catch by strata and whole bank data are presented. Length composition of the catch is presented in Table 16.

DISCUSSION.

Among main species in Flemish Cap cod is a demersal species that moves off the bottom in an unknown degree, American plaice is a benthic species and redfishes behaves like a pelagic species. With such a group of species the efficiency of a bottom trawl remains unclear. Sweep area abundance estimates, that are considered in general to underestimate stock abundance, when they are applied to benthic and pelagic species as presented in this paper may be particularly skewed.

Bottom trawl catch series can reflect changes in abundance of species caught quite efficiently only if the vertical distribution of population does not change in time. The use of abundances indices necessitates evaluation of the gear efficiency.

The presence of a pelagic fish species with a higher abundance than all demersal and benthic ones is a common feature in bank fisheries. Although bottom trawls are not efficient for small size pelagic species, when such species are so abundant in the area they are often present in bottom gears. Considering the inventory of species caught in the survey, it is remarkable the absence of a small size pelagic species. Echosounders indicated the possible presence of a different species in dense shoals quite rarely. Redfishes and shrimp seem to dominate the pelagic domain. Stomach contents of three main species: cod, American plaice and *S. marinus* were analysed in 1423 individuals (Canalejo et al. 1989). A small size pelagic species were not present in them also. American plaice had a characteristic diet of benthic organisms. Redfish feeded on shrimp, *Mictophyidae* and unidentified fishes. Cod feeded on shrimp and unidentified fishes but also on redfish and other finfishes: dogfish and cod. The role of pelagic species for redfish is consistent with its great abundance.

Mean catch in half our tow of main species in the bank was:

|                              |        |     |
|------------------------------|--------|-----|
| cod .....                    | 46.74  | Kgr |
| American plaice ....         | 15.01  | "   |
| <i>Sebastes marinus</i> .... | 19.28  | "   |
| <i>Sebastes</i> spp. ....    | 188.22 | "   |
| Shrimp .....                 | 2.5    | "   |
