Length-weight Relationships of Roundnose Grenadiers (*Coryphaenoides rupestris* Gunn.)
in Different Areas of the Northwest Atlantic

ABSTRACT

Length and weight information were obtained from roundnose grenadiers during research trawling in the areas of West Greenland and off Baffin Island (subareas 0 + 1), off northern Labrador (Div. 2G) and off Notre Dame Bay (Div. 3K) from 1968 to 1980. Comparisons by area and sex indicated some variability, possibly caused in part by differing habitat conditions. Relationships derived for grenadiers in Subarea 2 + Div. 3K indicate general consistency between studies, while results from subareas 0 + 1 are more variable. The results suggest that it may not be appropriate to utilize growth differences as indicators of differing stocks.

INTRODUCTION

The assessment of roundnose grenadier stocks in different areas of the north Atlantic is difficult because of the relatively deep distribution of these fish as well as a general lack of knowledge concerning their biology, population dynamics and life history. Traditional assessment methodologies such as analysis of research and/or trawling survey results, production models and sequential population analyses are not workable under current circumstances.

There is also relatively little known or understood concerning stock structure of these fish. At present, NAFO separates roundnose grenadier in subareas 0 + 1 from those in subareas 2 + 3 for assessment and quota purposes. In the past analyses of length weight relationships have been used to make inferences concerning inter-relationships between roundnose grenadier in different areas of the north Atlantic (eg. Atkinson 1989). This paper presents the results of analyses of length and weight data collected from various areas of the northwest Atlantic during 1968 - 1980 and makes comparisons with the findings of previous studies.

MATERIALS AND METHODS

The data were collected from West Greenland and off Baffin Island (subareas 0 + 1), off northern Labrador (Div. 2G) and off Notre Dame Bay (Div. 3K) from 1968 to 1980 by Soviet research and scouting vessels fishing with bottom trawls. Total lengths (nearest cm) and weights (gm) were recorded for only those fish considered to have unbroken tails. Each of these was also sexed. Prior to analyses, the fish were grouped into 3-cm groups (eg. 33-35, 36-38 cm etc.), and the mean weight for each group calculated (Tables 1 and 2).

Weighted (by the number of fish in each length group) regressions of the form:

$$W_{t_{gm}} = aL_{-cm}^b$$

were done by sex and area (SA 0, SA 1, Div. 2G and Div. 3K). In addition, the data for subareas 0 + 1 were combined by sex as were the data for divisions 2G + 3K and regression analyses carried out. Finally, regressions of the data for the above two areas were carried out with sexes combined.

Analyses of covariance were not carried out because of the large sample sizes. It was anticipated that statistically significant differences would exist between all curves.

Fulton's condition factor (Fulton 1911):

$$K_f = \frac{100W}{L^3}$$

was also calculated to compare males and females in subareas 0 + 1 and divisions 2G + 3K as well as make comparisons by sex between the two areas. Although this factor is most appropriately applied when growth is isometric, it may be used to compare fish of approximately the same length regardless of the value of b (Ricker 1975).

RESULTS AND DISCUSSION

Results of the regression analyses are summarized in Table 3. There were no large scale differences in the length-weight relationships between subareas 0 and 1 or divisions 2G and 3K when examined by sex (Figure 1). Similarly, there were no large differences when comparing relationships by sex for the two management units (Figure 2). There were differences between sexes in the two areas however (Figure 3). With the sexed data combined, very little difference was observed between the two management areas (Figure 4).

These results are somewhat different than those described by other authors (Savvatimsky 1970, Borrmann 1976, Atkinson 1980 and Atkinson 1989). Although most studies yielded quite similar results for subareas 2 + 3 (Figure 5), differing results have been obtained for the more northern area (Figure 5). The reasons for this are unknown.

Comparisons of Fulton's condition factors indicate differences between males and females in both areas, but no large differences between areas for either sex (Figure 6). The condition factor decreases with size in all cases.

It is most likely that the length-weight relationships for grenadier vary between seasons and years as is characteristic of other gadoids (eg. Postolaky 1978). The relationships will depend on the feeding activity of the fish as well as the relative weight of the liver and gonads. Savvatimsky (1982) has shown that the liver may constitute from 1 to 10 % of the body weight during different months of the year and this translates to weights between 5 and 50 gm depending on the size of fish. These changes may account, to a large degree, for the differences noted in the length-weight relationships derived from different areas and different studies. Prior to using this type of information to make inferences concerning population structure, it is necessary to consider when samples were collected, as well as fish condition at the time of collection.
