SCIENTIFIC COUNCIL MEETING - JUNE 1995

An Assessment of the Greenland Halibut Resource in
NAFO Subarea 2 and Divisions 3KLMN

by

W. R. Bowering, W. B. Brodie, D. Power, and M. J. Morgan

Science Branch, Department of Fisheries and Oceans
P. O. Box 5667, St. John's, Newfoundland, Canada A1C 5X1

Catch History and TACs

The fishery for Greenland halibut in Subarea 2 and Div. 3KLMN began in the early-1960s using synthetic gillnets in the deepwater bays of eastern Newfoundland particularly Trinity Bay. As catches declined here, the effort moved northward to Bonavista Bay, then Notre Dame Bay and finally White Bay on Newfoundland's northeast coast. Subsequently, vessels moved more offshore to the deep channels running between the shallow fishing banks. Catches increased from fairly low levels in the early-1960s to over 36,000 tons by 1969 and ranged from 24,000 tons to 39,000 tons over the next 15 years (Fig. 1). From 1986 to 1989, catches exceeded 20,000 tons only in 1987 (Table 1; Fig. 1). In 1990, a high effort fishery for Greenland halibut developed in the deepwater area of the NAFO Regulatory area near the boundary of Div. 3L and Div. 3M in areas known as the Sackville Spur and the Flemish Pass. The development of this fishery quickly resulted in increased catches to about 47,000 tons in 1990. It was estimated that the catch in 1991 was at least as high as 55,000 tons (Table 1; Fig. 1 and 2) although some estimates put the catch at nearer 75,000 tons. Catches during 1992 and 1993 remained high and were estimated to be about 63,000 and 62,000 tons, respectively. Best estimates of catch suggested a decline to about 48,000 tons during 1994 although some estimates ranged as high as 56,000 tons. The major participants in this fishery have been EU/Spain and EU/Portugal, as well as a variety of non NAFO-member countries such as Panama although by 1994, more than 80% of the catch is estimated to have been caught by EU (Spain) alone. Catches listed as "Subarea 3 Outside" in Table 1 include all non-Canadian catches during recent years and are illustrated in Fig. 2 for comparison with traditional fishing areas of Subarea 2 and 3 inside the Canadian zone.

Up until 1990, Canada, USSR, GDR, and Poland were usually the main participants in the fishery, although Portugal and Japan had become increasingly involved in the fishery since 1984.

Canadian catches have been taken mostly by gillnet with a significant proportion taken by otter trawlers. With the exception of 1987, catches have been declining steadily inside the Canadian zone since the early 1980's from a high of 30,000 tons to less than 3,000 tons by 1994. This declining trend was a result of reduced catch rates, low prices and multi-licensed vessels fishing other species that offered a better return on costs.

The traditional gillnet fishery has been conducted by relatively small vessels (<20 m) fishing in the deepwater channels near the Newfoundland and Labrador coast as well as the Newfoundland east coast deepwater bays. However, this component of the fishery has declined rapidly in recent years and has now virtually collapsed due to very low abundance of fishable stock in traditional areas. The Canadian gillnet catches taken during recent years are from a newly developed fishery along the deep edge of the continental slope especially in Div. 3KL and Div. 2G although some catches are also taken in Div. 2H and 2J (Table 1).

Canadian otter trawl catches peaked at about 8,000 tons in 1982, declined to less than 1,000 tons in 1988, then increased to about 7,400 tons in 1991 which is the highest level since 1982. In 1992, otter trawl catches were less than half that of 1991 due to low catch rates. The catch in 1993 was just over 1,500 tons and by 1994 was less than 600 tons. Catch rates were very poor due to the low abundance of fish larger than 45 cm.

The TAC for this resource in Subarea 2 and Div. 3KL only, increased from 35,000 tons in 1980 to 55,000 tons in 1981-84, 75,000 tons in 1985, and 100,000 tons in 1986-89 (Fig. 1). These increases in TACs were the result of research vessel survey estimates of stock biomass (in excess of 400,000 tons) which indicated both high levels of fishable biomass as well as prospects of several better than average recruiting year-classes. After observing an estimated reduction in stock biomass from the late-1970s to the late-1980s in Subarea 2 and Div. 3KL of about 50%, the TAC was reduced to 50,000 tons in 1990 and this level was maintained to 1993 despite the substantive declines in stock size throughout the normal range of observed historical stock distribution. Although the Scientific Council, in its deliberations during June 1993, could not advise an appropriate catch level for 1994 the TAC was reduced to 25,000 tons by Canada in Subarea 2 and Divisions 3KL in consideration of low levels of stock size estimated for the area. It was intended that this catch should include all catches in the area of Subarea 2 and 3 for conservation purposes.

In 1994, management responsibility of Greenland halibut in Subarea 2 and Div. 3KLMN was accepted by the NAFO Fisheries Commission which imposed a TAC of 27,000 tons for 1995.

Commercial Fishery Data

i) Catch and effort

A detailed analysis of all available catch and effort data from both the inshore and offshore gillnet fisheries and offshore trawlers has been undertaken and is presented in another document (this meeting).

ii) Catch-at-age and mean weights-at-age

Sampling data from the catches of Canada in 1994 were not processed in time to be available for this meeting.

Due to uncertainty regarding catch information on fisheries in the Regulatory Area, catch-at-age for Canadian catch only were calculated for 1988-93 for the purpose of this document. Catch numbers-at-age and catch weights -at-age (kg) for these data are presented in Tables 2 and 3. The data prior to 1989 represent the entire annual fishery (Tables 4 and 5).

Ages 6-8 dominated the catch in most years up to 1991 (Table 2 and 4), which is typical of the traditional Canadian catch. Although the Canadian catch was much lower in 1992 and 1993 than in previous years, there were significant increases in the proportions of older fish (ages 9-13) (Table 2) in the catch. This is due to a considerable change in the fishing pattern with exploitation of Greenland halibut now mainly in the deepwater along the continental slope by gillnetters using a 200 mm mesh size in depths greater than 1000 m compared to a 130-190 mm mesh size at depths of less than 500 m. Although data were not available for the Canadian fishery in 1994, the fishery was conducted in a similar manner as that in 1992 and 1993 predominated by the same NAFO divisions (Table 1).

Research Vessel Surveys

i) Biomass and abundance indices

Biomass estimates from Canadian stratified-random groundfish surveys in autumn in Div. 2J for 1977-92 are presented in Table 6. Due to a revision of the stratification scheme in 1993 strata are not directly comparable, therefore, the results for Div. 2J in 1993-94 are presented separately in Table 7. Similarly, the biomass estimates for Div. 3K during 1978-92 and 1993-94 are shown in Tables 8 and 9, respectively. Biomass indices from autumn surveys in Div. 3L, during 1981-94 are detailed in Table 10. In all cases the total annual biomass estimates are accompanied by 95% confidence limits. Annual biomass estimates are also illustrated by division separately in Fig. 3 and cumulatively for Div. 2J, 3K and 3L in Fig. 4.

It should be noted that in Div. 2J and 3K, the strata from 1001-1500 m were rarely surveyed and thus were not included in the indices. In Div. 3L, the deepest strata are only 732 m, and these areas were not surveyed in all years. No Canadian survey data are available in Div. 2GH since those presented in Brodie and Baird (1992).

Cumulative abundance indices at age from Div. 2J, 3K and 3L are provided in Table 11 and illustrated by year in Fig. 5. A summary of annual abundance by various age groups i.e. Ages 1+; Ages 3-5; Ages 6-9; Ages 10+ are also shown in Fig. 5. Although there were no surveys in the fall of 1978-80 in Div. 3L estimates of abundance were obtained for these years by averaging estimates from spring surveys of adjacent years.

Biomass indices of Greenland halibut have been declining in Div. 2J since 1982 from a level of over 100,000 tons to less than 9,000 tons by 1992 (Table 6; Fig. 3 and 4). There was a slight increase in 1993 to near that of 1991 (Table 7) but still at a very low level. The 1994 estimate is similar to that of the previous year (Table 7). The biomass index in Div. 3K peaked at 112,000 tons in 1984 but by 1987 biomass in this division also began a steep decline similar to Div. 2J and reached a low of just over 20,000 tons in 1992 (Table 8; Fig. 3 and 4). In 1993, there was a similar proportional increase in biomass as in Div. 2J to a level slightly lower than that of 1991. The 1994 survey, however, estimated the biomass to be at the same level as indicated for 1992 which is the lowest in the time series (Table 9). Estimates for Div. 3L to a depth of 366 meters were relatively stable from 1981 to 1990 at about 15,000 tons (Table 10; Fig. 3 and 4). Between 1990 and 1991, the biomass index fell from nearly 17,000 tons to 7,300 tons and further to 6,700 tons in 1992 despite the fact that survey coverage in 1991-92 was complete to depths of more than 720 meters. Unlike the divisions to the north the biomass estimate in Div. 3L in 1993 declined from that of 1992 to a level near half the 1991 and 1992 estimates and is the lowest during the period. The 1994 estimate continues to be low and is within a 10% variation of the 1993 estimate (Table 10).

The cumulative biomass index for all three divisions (Fig. 4) has steadily declined from a high of over 200,000 tons in 1984 to 37,000 tons in 1992 by far the lowest in the time series. Although the overall index increased to nearly 50,000 tons in 1993, the 1994 estimate returned to the 1992 level of 37,000 tons (Fig. 4).

Declines in abundance are less apparent than indicated by the biomass indices due to the fact that the declines are not consistent across all age classes (Table 11; Fig. 5 and 6). An examination of the age structure in Fig. 5 and 6 shows that the ages 6-9 abundance has been declining possibly since the mid 1980's but very dramatically since 1990 and by 1993 and again in 1994 the age 6-9 abundance is far below anything ever observed. It is now at a level of about one third of that estimated in 1992 and less than 10% of the 1982-90 average. Age 10+ has been declining since the early 1980's and in 1993 and 1994 had virtually disappeared from the survey catches. On the other hand, ages 3-5 were slowly increasing from the early 1980's to about 1989. From 1989 to 1992, however, these age groups also declined to a relatively low level at less than half the 1988 estimate. The index for these ages increased sharply in 1993 to the second highest in the time series and was maintained at a relatively high level in the 1994 survey (Fig. 5).

ii) Recruitment indices and year-class strengths

In order to better examine strengths of recruiting year-classes the trends in the abundance indices for individual ages 1-5, inclusive from fall surveys in Div. 2J and 3K combined are presented in Fig. 7 with 95% confidence limits. In addition, trends in individual ages 2-10 from Table 11 are presented in Fig 8 to compare pre-recruiting age groups with the major age groups comprising the commercial fishery.

There would appear to be little useful information in the estimates at age 1 as they are poorly recruited to even the survey trawl, show little in the way of trends and have relatively high confidence limits (Fig. 7).

At age 2 the estimates for most years are much more stable with tighter confidence limits. The 1991 year-class estimate at age 2 is significantly larger than any other in the time series with the 1992 year-class also estimated to be larger than any in the previous 10 years although to a much lesser degree than that of the 1991 year-class. The 1990 year-class estimate appears about average but variable (Fig. 7).

At age 3 the 1990 year-class estimate is significantly larger than any other in the time series by a wide margin despite the fact that it only appeared average at age 2 above. The 1991

year-class was also larger than anything previously estimated at age 3 although much smaller relatively than that of the 1990 year-class (Fig. 7).

At age 4, the 1970's year-classes all appear to be weaker than those of the mid to late 1980's. The 1990 year-class is estimated to be similar in strength to those year-classes at the higher end of the range of estimates (Fig. 7).

At age 5 the trend is similar to age 4 up about the 1990 survey year beyond which all estimates at this age declined considerably to the point that the most recent three estimates are below anything that has been observed in previous years (Fig. 7).

The major commercial age groups (ages 6-10) have been declining at rapid rates individually for a number of years (Fig. 8). For ages 5, 6 and 7, trends in abundance were rather stable until about 1990 when steep declines occurred. For ages 8, 9 and 10, however, the declines appear to have begun at some earlier time probably about the mid to late 1980's.

It has been hypothesized that the very steep declining trend in the stock component in at least Div. 2J and 3K, is a result of a migration southeast to the Flemish Pass area. This occurred at a time that is coincident with the build up of considerable fishing effort and subsequently, very high catch levels which have now depleted the stock of larger, older fish. While the number of larger, older fish remains low according to current survey data, there continues to be indications of average to better than average 'pre-recruit' year-classes similar to those observed in the previous assessment.

Given the observation above with respect to the diverging abundance pattern between ages 4 and 5 since 1990, the ratio of the same year classes at these ages is presented in Figure 9. Generally, the average ratio is between 1.25 and 1.6 from 1978-88 indicating that Greenland halibut at age 4 are not fully recruited to the survey gear. From 1988-90 the ratio dropped substantially to about 0.5 in 1990 and remained at that level to 1994. It is suggested that between 1988 and 1990 a significant change occurred in migration and/or mortality and the pattern remained to the present. It may be hypothesized that recruits migrate from the survey area in the north in abundance and this migration occurs between ages 4 and 5 and probably move to the Regulatory Area.

iii) Combined abundance-at-age

In order to derive a more complete abundance index at age from the data available, the survey catch at age from the fall surveys in Div. 2J and 3KL for 1991 and 1993-94 is combined with the catch data age from the deepwater surveys in Div. 3KLM in 1991 and 1994-95 (appropriately lagged) and presented in Figure 10. With the exception of Div. 2J the figures represent estimates to a maximum depth of 1500 meters. The maximum depth for Div. 2J is 1000 meters. Estimates for commonly surveyed areas are not included to avoid double counting.

The results indicate that the area surveyed during the regular fall surveys account for most of the estimates at all ages (Fig. 10). It also suggests that there has been an overall decline in the abundance between 1993 and 1994 (fall equivalent). However, in both years the 1990 and 1991 year classes comprise most of the observed abundance.

Table 1. Catches of Greenland halibut in the Northwest Atlantic by division and selected areas from 1977-94.

Year	Div. 2G	Div. 2H	Div. 2J	Div. 3K	Div. 3L Inside	Total Inside	Subarea 3L Outside	Overall Total
