Abstract

Since 1988 has Greenland Institute of Natural Resources annually conducted a bottom trawl survey off West Greenland. The main purpose of the survey is to evaluate the biomass and abundance of Northern shrimp (*Pandalus borealis*), but data on most fish species have been recorded. This paper presents biomass and abundance estimates together with length frequencies of cod, Greenland halibut, redfish and other economical and ecological important species from the survey area.

Greenland halibut was found in all divisions, but it was most common in Div. 1AN-1BN. In 1999 the biomass and abundance was estimated to 294 million individuals and 23137 tons. The length distribution ranged between 6 and 42 cm with two clear modes around 15 cm and 23 cm.

Redfish was found in all the survey areas, but was usually most common in Div. 1BN and 1C. In recent years the abundance and biomass has decreased. In 1999 the catches comprised almost exclusively of species less than 20 cm.

Cod is mainly caught south of 68°00'N. Biomass and abundance indices in 1999 were estimated to only 60000 individuals and 115 tons. Too few cod observations were available for length distributions.

Introduction

Since 1988 has Greenland Institute of Natural Resources annually conducted a bottom trawl survey off West Greenland. The main purpose of the survey is to evaluate the biomass and abundance of Northern shrimp (*Pandalus borealis*), but data on most fish species have been recorded. This paper presents biomass and abundance estimates together with length frequencies of cod, Greenland halibut, redfish and other economical and ecological important species from the survey area.

Materials and Methods

The survey covers the offshore areas at West Greenland between 59°00'N and 72°30'N from the 3-mile limit to the 600 m depth contour line and the inshore area Disko Bay (Figure 1 and Table 1). The survey area is divided into NAFO

Divisions, which were further subdivided into three depth strata (0-200, 201- 400 and 401- 600 m) on basis of depth contour lines. The area surveyed has, however, changed throughout the years. From 1988 to 1990 the survey area included Div. 1AN to 1D. In 1991 the Div. 1AN was not covered. In 1992 the survey area was extended to include Div. 1AN to 1F and Disko Bay (Div. 1AX), and this area is now surveyed annually. The survey was originally designed as a shrimp survey and sampling of fish data was not complete in the period 1988-1991. Since 1992 the sampling of fish has improved and the survey is now considered as a combined groundfish/shrimp survey. The survey period was July to September.

The survey is designed as a stratified-random trawl survey. A minimum of two hauls per stratum is always planned. Due to lack of information of the bottom topography Div. 1AN and Disko Bay are considered as two single strata. The number of valid hauls by year and stratum is listed in Table 2.

The surveys have been conducted with trawlers of the same size throughout the years. Since 1991 the 722 GRT stern trawler M/Tr 'Pâmiut' has been used. The trawl is a Skjervoy 3000/20 with bobbin gear and double bag. The mesh size in the codend was 40mm from 1988 to 1992. From 1993 the mesh size in the codend has been 20 mm. The changes of mesh size did not influence the catch ability of fish except for redfish abundance. Abundance estimates for redfish before 1993 are therefore adjusted in accordance to Bech 1994. The trawl doors in use are of the type 'Perfect', except for the 1989 survey where 'BMV' doors were used. Wing spread is fixed at 18,956 m.

The standard trawling time offshore is 15-60 minutes at a mean towing speed of 2.5 knots. In Disko Bay (1AX) the trawling time is 30 min. The trawling operations are performed during daytime only.

After each haul the catch was sorted by species or lowest taxonomic level and weighed to 0.1 kg and the number recorded. Fish was measured as total length to 1 cm below. The caches of redfish consisted almost exclusively of specimens <20 cm. Due to difficulties in identification of species all redfish were classified as *Sebastes sp.*.

Stratified abundance and biomass estimates were calculated from catch-per-tow data using the stratum areas as weighting factor (Cochran, 1953). The coefficient of catchability was set at 1.0, implying that estimates are merely indices of abundance and biomass. Confidence intervals (CI) were set at the 95% level of significance of the stratified mean.

Catch per unit effort (CPUE) for Greenland halibut was calculated in numbers pr year-class per hour. Age distributions of Greenland halibut were estimated on the basis of otolith reading.

Results

Greenland halibut (*Reinhardtius hippoglossoides*)

Greenland halibut was found in all divisions, but it was most common in Div. 1AN-1BN. In 1999 the biomass and abundance was estimated to 294 million individuals and 23137 tons (Table 5 and 4). Distribution of survey catches in kg pr. hour and number pr. hour are shown in Figure 1 and Figure 2 for 1999. High abundance are especially found in Div. 1AX (Disko Bay). The abundance and biomass estimates in the period 1992-1995 have been relatively stable with 270-345 mill individuals and 11000-14000 tons. In 1996 the abundance increased to 603 mill. individuals, which is the largest figure in the time series, and has since declined to the present level. The biomass shows a slight increasing trend during the time series.

The length distribution ranged between 6 and 42 cm with two clear modes around 15 cm and 23 cm (Figure 3). A similar pattern was seen in 1998, whereas in previous years modes were found around 10-13 cm, 18, and 25 cm.

The CPUE (number per age per hour of age 1 (1998 year class) was estimated at 223 and 496 specimens in 1999 in the offshore nursery area (Div. 1AS, 1BN and 1BS) and in the Disko Bay, respectively (Figure 4). The 1997 year-class the largest in the time series for the Disko Bay and the 1998 year class is also high, but the similar year classes are only around average for the offshore area.

Redfish (*Sebastes sp.*).

Redfish was found in all the survey areas, but was usually most common in Div. 1BN and 1C. Distribution of survey catches of redfish sp. in kg pr. hour and number pr. hour are shown in Figure 5 and Figure 6 for 1999.

Tables 5 and 6 list abundance and biomass indices by stratum. The abundance and biomass estimated in the period 1992-1996 have fluctuated without a clear trend between 1.1-2.8 billion individuals and 12000-31000 tons. In recent years the abundance and biomass has decreased from 4.7 billion individuals and 60497 tons in 1997 to 464 millions individuals and 12668 tons in 1999 (Table 5 and 6). This decrease is particular distinct for stratum 1BN.

In 1999 the catches comprised almost exclusively of species less than 20 cm. In previous years annual growth increments of 4 cm were indicated by pronounced peaks in length compositions at 7-8 cm and 12 cm probably corresponding to age 1 and 2 (Figure 7) (Nederaas, 1990). The 1999-survey revealed only a small peak at 10 cm, leaving no sign of the very prominent 1996-yearclass seen in previous surveys.

American plaice (*Hippoglossoides platessoides*).

American plaice is mainly found in Div. 1A-1D. In 1999 the biomass and abundance was estimated to 23 million individuals and 1193 tons (Table 7 and 8). The abundance and biomass estimates for American plaice has varied without any significant trend between 9 and 48 millions individuals and 656 and 1951 tons. In 1999 the length ranged between 5 and 35 cm (Figure 8). A clear mode at 10-12 and somewhat weaker modes at 15-20, 23-25 and 30-32 cm are found in 1999 as well as in previous years.

Spotted wolffish (*Anarhichas minor*)

Spotted wolffish is evenly distributed in the survey area. In 1999 the biomass and abundance was estimated to 1,6 million individuals and 386 tons (Table 9 and 10). The abundance and biomass has varied through the time series without any significant trend with highest estimates in 1994 (1,3 million individuals and 705 tons) and lowest in 1993 (283000 individuals and 413 tons). Too few observations of spotted wolffish were given in the surveys during the years to reveal meaningful length distributions.

Atlantic wolffish (*Anarhichas lupus*)

Atlantic wolffish is mainly caught south of 68°00'N (Table 11 and 12). In 1999 the abundance and biomass was estimated to 1,8 million individuals and 302 tons.

The abundance and biomass has varied through the time series without any significant trend with highest estimates in 1994 (6,7 million individuals and 977 tons) and lowest in 1993 (1,0 million individuals and 228 tons). In 1999 the length ranged between 5 and 50 cm (Figure 9). The analysis of the length distribution reveal the dominance of small fish<35cm but no particular pattern.

Cod (*Gadus morhua*).

Cod is mainly caught south of 68°00'N. Tables 13 and 14 list abundance and biomass indices of cod by stratum. The biomass-indices for cod were estimated to 4,000-7,000 tons in 1988-1990. In 1992 the biomass decreased with over 95% to only 250 tons and 528,000 individuals and has remained at this low ever since. Biomass and abundance indices in 1999 were estimated to only 60000 individuals and 115 tons. Too few cod observations were given in the 1999 survey to reveal a meaningful length distributions. The length of cod in previous surveys ranged between 15 and 60 cm with distinct modes 23-27 cm in 1992 and in 1995.

Starry skate (*Raja radiata*)

The biomass is mainly distributed in Div. 1A-1D. The abundance and biomass of starry skate have increased from a level about 6-10 million individuals and 7-12,000 tons in 1991-1993 to a level of 13-16 million individuals and 2000-3000 tons in 1994-1998 (Table 15 and 16). In 1999 the abundance and biomass has decreased again to 11 millions individuals

and 1660 tons respectively.

No length data are available for this species.

Discussion

The survey was originally designed as a shrimp survey. The fish data are incomplete and the survey did not cover the same area in the period 1988-1991. Direct comparison was hence only possible for the period 1992-1999. The main purpose of the survey is to evaluate the biomass of northern shrimp and most effort is concentrated in the areas and depths where the commercial shrimp trawling taking place, especially on the northern slopes of the grand bank Store Hellefiskebanke ($67^{\circ}50'N$ $55^{\circ}00'W$) and in the inshore area Disko Bay. As Store Hellefiskebanke and Disko Bay are important nursery areas for Greenland halibut and redfish as well as other important species (Smidt 1969; Tåning 1949) it is likely, that the abundance and biomasses estimates of the survey reflects the juvenile stock situation of these species. The results of the survey indicate a very high mortality rate on one-year-old redfish - and Greenland halibut, and indicate migration from offshore areas towards Disko Bay. Apart from an annually fishery of about 5500 tons Greenland halibut, no fishing effort has in recent years been directed towards groundfish off West Greenland, but an extensive shrimp fishing on traditional fishing grounds is suspected to have a negative effect on the survival rates of recruits. The fishable part of all ground fish stocks have in recent years been severely depleted (Rätz 1998a Rätz 1998b; Ogawa et al. 1994; Yokawa et al. 1995). The low biomass and abundance of cod, American plaice, wolffish and stary skate presented in this paper supports this general picture. The survey results do indicate a continued recruitment of Greenland halibut, whereas the recent recruitment of redfish has been very low.
