SCIENTIFIC COUNCIL MEETING – JUNE 2016

Estimation of By Catch in the Commercial Fishery for Greenland halibut at West Greenland based on Survey Data

Ole A. Jørgensen
DTU-Aqua, Technical University of Denmark
Charlottenlund Slot, 2920 Charlottenlund, Denmark

Abstract

The by catch in the commercial fishery for Greenland halibut in NAFO Div. 1CD was estimated based on information from ground fish surveys conducted by Greenland Institute of Natural Resources in the same area as the commercial fishery. The survey is conducted with a trawl with 30 mm in the cod end while the minimum mesh size in the cod end in the commercial trawls is 140 mm and the survey catches are converted to potential commercial by catches. The conversion is based on a number of assumptions and the results should be considered as indicative. The total by-catch in weight is estimated to be 13% of the total catch of Greenland halibut. *Macrourus berglax* is the most abundant by catch species and constituted 3.2% of the weight of Greenland halibut followed by *Antiomora rostrata* (2.7%), *Alepocephalus agassizzi* (2.0%) and *Hydrolagus affinis* (1.2%). None of the remaining species constituted more than 1% of the weight of the Greenland halibut catches. The impact of the fishery for Greenland halibut in Div. 1CD on the stocks of the by-catch species seems, however, to be limited. The by-catch in Div. 0B is at the same level as in Div. 1CD.

Introduction

By catch in the commercial fisheries has become an increasing issue and is an important parameter in evaluation of the sustainability of the fisheries. The information about by catch in the commercial fishery for Greenland halibut (*Reinhardtius hippoglossoides*) at West Greenland (NAFO SA 1) is limited and the information in the log books is sparse and there is no direct information from other sources.

In the present paper the by catch in the commercial fishery for Greenland halibut in NAFO Div. 1CD is estimated based on information from ground fish surveys conducted by Greenland Institute of Natural Resources in the same area as the commercial fishery. The survey is conducted with a trawl with 30 mm in the cod end while the minimum mesh size in the cod end is 140 mm and the survey catches is converted to potential commercial by catches.

It has not been possible to estimate the by catch in the Baffin Bay (NAFO Div. 1AB) due to too few survey hauls in the area and at depths where the commercial fishery takes place to make reasonable by catch estimates. The most abundant species in the by catches in Div. 1CD *Macrourus berglax*, *Antiomora rostrata*, *Alepocephalus agassizzi* and *Hydrolagus affinis* were, however, ether total absent or very rare in the survey catches in Div. 1AB, where the commercial by catch probably is dominated by *Amblyraja hyperbore*a and *Anarhichas denticulatus*.

Material and methods

The survey takes place in September and covers NAFO Div. 1CD at depths between 400 and 1500 m, which is the same area as the commercial fishery is conducted. 90% of the commercial trawl hauls takes place at depths > 941 m (mean 1096 m). Survey trawl hauls > 941 m from 2010-2014 are selected for analysis, 178 hauls in total. The survey is assumed to have a catchability on 1 *i.e*. all fish in the trawled area are caught.

The survey is conducted with 30 mm mesh in the cod end while the minimum mesh size is 140 mm in the commercial fishery. There are no selection data available for the relevant species. In order to convert survey catches to commercial catches the selection of round fish is set to 3 times mesh size *i.e*. 42 cm and 1.5 times mesh size for rays and skates *i.e*. 21 cm as a rule of thumb. There are no flatfish observed in the survey catches at the depth rang used in the analysis. The minimum landing size for Greenland halibut is 42 cm and it is considered to be fully selected to the commercial gear at that length.

A number of fish species caught in the survey are considered to be pelagic, and hence only be caught while the trawl is set or hauled, and/or too small (Whitehead et al. 1984) to be taken in a 140 mm trawl, or having a body shape that should allow them to escape a 140 mm trawl. These species are excluded from the estimations (Table 1).

Among the remaining species there are specimens that are too small to be selected in a 140 mm trawl. The weight of these small fish is estimated by length-weight relationships obtained from the literature or Fish Base. The estimated weight of small fish is subtracted from the total survey catch weight of the species and the weight of the remaining "large" fish is given as percentage of the survey catch weight of Greenland halibut > 41 cm.

Grenadiers are measured as Anal Fin Length in the survey but is converted to total length (Jørgensen 1996).

Results

In total 90 species or species groups were caught in the surveys (Table 1). 62 of them are considered to be pelagic and hence only be caught while the trawl is set or hauled and/or too small (Whitehead et al. 1984) to be selected in a 140 mm trawl, or having a body shape that should allow them to escape a 140 mm trawl (eg: *Anoptopterus pharo*, *Eurypharynx pelecanoides*, *Sacopharynx ampullaceus*, *Serrivomer beani, Synaphobranchs kaupi* and *Lycodes species*.

The by catch in weight is estimated to constitute 13.0% of the weight of Greenland halibut > 41 cm (Table 2). *Macrourus berglax* is the most abundant by catch species. The length in the survey catches ranged from 14-102 cm and the weight of fish < 42 cm was estimated to 212.0 kg, while the weight of fish > 41 cm was estimated to 842.5 kg, which is 3.22% of the weight of Greenland halibut > 41 cm. The second most abundant species was *Antiomora rostrata* that constituted 2.70% of the weight of Greenland halibut, followed by *Alepocephalus agassizzi* (2.02%) and *Hydrolagus affinis* (1.19%). None of the remaining species constituted more than 1% of the weight of Greenland halibut (Table 2).

Discussion

The estimations are based on 178 survey trawl hauls conducted in the area and at depths where the commercial fishery for Greenland halibut in NAFO Div. 1CD takes place which gives a reasonable good coverage of the area.

The estimations are based on a number of assumptions and the results should be considered as indicative:

1) There are no selection parameters available for the relevant species and a knife edge selection has been used for all species. Further, the same knife edge selection on 42 cm and 21 cm has been applied for roundfish and rays and skates, respectively, despite that fish has a very different shape as *eg. Notacanthus chemnitzii, Macrourus berglax* and *Antimora rostrata.*

2) The weight of small fish < 42 (roundfish) and < 21 cm (skates and rays) is estimated from length/weight relationships from the literature and are usually not from the survey area, which could either underestimate or overestimate the weight of small fish.

3) Grenadier lengths are converted from Anal Fin length to total length. This convention is, however, based on data from the area (Jørgensen 1996).

4) A 42 cm Greenland halibut, which is the minimum landing size, is considered to be fully selected to the commercial gear. This assumption is probably acceptable. The discard from the commercial fishery is reported to be < 1% (Jørgensen and Treble 2015) and must include damaged fish that cannot be processed.

The selection in a commercial trawl that has been fishing for hours and hence could contain several tons Greenland halibut is probably not fully effective which implies that some small fish including some pelagic species distributed close to the bottom are caught in the trawl. The proportion of this type of catch can only be estimated by direct analysis of the commercial catches.

The fishery for Greenland halibut at West Greenland is conducted in a rather small area compared with the much wider distribution area of almost all spices observed in the area (Whitehead et al. 1986), and many of the species are at the rim of their distribution area (Jørgensen et al. 2011), suggesting that stock dynamic processes outside the fishing area might influence the dynamics of these stocks within the fishing area. A study by Jørgensen et al. (2014) showed hence that the effect of the Greenland halibut fishery in Div. 1CD on the abundance of non-commercial species is limited while a number of species decrease in mean size. During the period 1988-2011 *Macrourus berglax* showed an increase in abundance while the mean sizes decreased about 15%. The changes were, however, not statistically significant. The second most abundant by catch species *Antiomora rostrata* showed a statistically significant increase in abundance (p=0.001) while the mean size decreased by about 30% (p=0.001). The abundance of *Centrocyllium fabrici* decreased statistically insignificant (0.05 level) while the means size decreased 26% (p=0.05), There is no information on *Alepocephalus agassizzi* and *Hydrolagus affinis* in the paper.

In SA 0 (Canadian waters) the by-catch is estimated by observers on board and the observer program covers most of the catches. In 2015 the by-catch in the trawl fishery in Div. 0B was estimated at 16.3% of the Greenland halibut catches which is in good agreement with what is estimated for Div. 1CD. The by-catch in the trawl fishery in Div. 0A was estimated at 6.7%. Greenland shark, skates and roughhead grenadier were the dominant by-catch species in SA0 (Jørgensen and Treble 2016) .

Table 1. Species caught in survey hauls > 941 m. Species marked * is consider to be pelagic, having too small a maximum size or having a body shape that does that they are not selected by a 140 mm trawl.
