ANNUAL MEETING - JUNE 1976

Estimation of stock size and allowable catch of silver hake
on the Nova Scotia Shelf in IICNAF Division 4W

by

A.S. Noskov
AtlantNIRO
Kaliningrad, USSR

INTRODUCTION

Silver hake is one of the major fishery objects in the Nova Scotia area. The bulk of the landings by the USSR come from Sub-area 4W. In the present report the stock assessments by VPA, and the calculations of allowable catch for 1977 at different natural and fishing mortality rates are given.

LANDINGS

Before 1962 silver hake from Nova Scotia area was taken as a by-catch in the fisheries of other fish species. Beginning from 1962 the Soviet fleet began to fish silver hake directly. Landings increased rapidly from 8854 tons in 1962 to 123028 tons in 1963. Then landings declined to 81147 tons in 1964, and in 1967, 1968 they decreased to 2477 and 3447 tons, respectively. From 1969 landings increased again numbering maximum of 298621 tons in 1973, then declined (Table 1). A 1964-1968 landing decline can be attributed to decreased stock size due to recruitment of a series of the poor 1961-1965 year-classes. In the period from 1966 to 1974 the stocks were supplemented by a new year-class series of high and average abundance, and a sharp landing increase followed.

Landing decline in 1974 and 1975 can be first of all explained by introduction of the limits into the hake fishery.

DISTRIBUTION

Major silver hake concentrations are distributed in the Eme-Deep area in winter moving in spring through the trough to the continental slope, where the concentrations between the La Have Bank and the Deep of Hali are formed by the end of summer. With heating of water silver hake concentrations move to the shoals off the Sable Island where the spawning takes place. Smaller concentrations of hake are located on the Georges Bank slopes. Massive hake spawning in the Georges Bank area occurs in June. It is likely that a small separate hake stock does occur on the Georges Bank, while in the Sable Island area (4V and 4W) an abundant silver hake stock is fished, which contributes on the average 90% of landings from Subarea 4. Therefore, the stock size assessment is made for Subarea 4.

CATCH COMPOSITION

Silver hake catch composition has been studied by means of massive measurements on board the commercial vessels and simultaneous collection of otolith samples for age determination. A fork length of fishes was measured to the nearest centimetre. The age was read by whole otoliths placed in dark alcohol containing cuvette, and examined under a binocular in reflected light. At present the USA ichthyologists have changed the methods of age reading. They begin age reading from thin otolith sections and come to a conclusion that the former determinations of silver hake age from the whole otoliths are overestimated, although the life cycle of silver hake appeared short according to the former determinations as well. The bulk of this species population is represented by age 1-5 fish. It is evident from Table 2 that the fish of 27.2 to 31.3 cm in length predominated in the landings. Mean length in 1962-1975 fluctuated from 27.2 to 31.3 cm. Age composition of catches for 1973-1975 is given in Table 3. In catches silver hake was represented by the individuals at age 1-12, while the bulk of the catches was made of the 3.4-5 year old fish. It should

be remembered that the number of 5 year old fish was increased in the years of depression, which can be attributed to a decline in recruitment.

GROWTH

The data on linear and weight composition as well as von Bertalanffy growth parameters, we adopted from the paper by R.G.Halliday (ICNAF Res. Doc. 73/103).

AGE	LENGTH, cm	WEIGHT, g
1	14.0	-
2	23.3	95
3	27.4	151
4	30.7	214
5	34.0	319
6	36.8	478
7	41.6	550
8	44.6	636
9	47.9	845

According to Halliday , von Bertalanffy growth parameters for ages 4 - 9 are as follows :

$$L_{\infty} = 52.67 \text{ cm } (W_{\infty} = 1.18 \text{ kg})$$

$$K = 0.229 \text{ and } t_0 = 0.141$$

MORTALITY

For estimation of total mortality silver hake catches per hauling hour by BMRT - class vessel transformed in age composition for 1970-1975 were used (Tables 4 and 5). For silver hake made the bulk of the catches in these years, it can be admitted that the fishing effort was directed to hake removal only. Total instantaneous mortality at age 3 and older changed from 0.35 to 1.58 . At the beginning of fishing activities in 1962-1969 it equalled 1.5 . In the Browns Bank area where the fishery for hake is insignificant and, therefore, does not greatly effect the stock size, the value of Z for age groups 3-6 averaged to 0.93 in the period from 1970 to 1974.

These data suggest that the natural mortality rate ranged between 0.5 and 0.9 . Therefore, the estimations of fishing mor-

tality and stock size by virtual population analysis are made for two values of $M = 0.5$ and 0.8 . The values of F estimated by VPA are given in Tables 6 and 7. The data in Table 6 indicate that F ranged from 0.03 to 2.27 by years if $M = 0.5$ at mean age 3 and older, and in 1974 it was 0.66. If $M = 0.8$, F ranged from 0.01 to 1.01.

STOCK SIZE

The stock size estimated by VPA at $M = 0.5$ and 0.8 is presented in Tables 8 and 9. When estimating the abundance of the 1973 and 1975 year-classes it was admitted that their numbers at age 1 equalled to mean abundance for 1968-1972. The 1974 year-class was strong and its abundance at age 2 was equalled to mean value of numerous 1968-1969 years-classes.

The results of trawling surveys on abundance conducted by "Belogorsk" in the Emerald Deep area are also indicative of high abundance of the 1974 year-class. So, from Table 10 it is evident that the youngs-of-the-year with the length ranging from 5 to 10 cm were taken in large numbers in October 1974, and in 1975 hake landings increased twice due to the rich 1974 year-class. This fact suggests that silver hake abundance in 1975 increased significantly as compared with 1974.

To estimate the optimal fishing effort the optimal age of exploitation was determined by the formula of Kutty M.K. and Qasim S.Z. (1968):

$$t'_{p} = \frac{\ln(3K + M) \ln M}{K} + t_0 .$$

L_c - the body length at which the fish is first exploited - is determined by von Bertalanffy equation:

$$L_c = L_{\infty} (1 - e^{-K(t'_{p} - t_0)}).$$

In calculations the following parameters were used:

$$L_{\infty} = 52.67 \text{ cm};$$

$$K = 0.23;$$

$$t_0 = 0.141;$$

$$M = 0.5 \text{ and } 0.8.$$

If $M = 0.5$, $t'_{\text{p}} = 3.91$, $L_c = 30.38 \text{ cm}$.

If $M = 0.8$, $t'_{\text{p}} = 2.84$, $L_c = 24.33 \text{ cm}$.

Then the values of $C = L_c/S_{\infty}$ and $E = \frac{F}{F+M}$ were estimated, and by Beverton and Holt Tables (1968) a dependence of yield on recruitment, Y/R , was determined (Fig.1), as well as F_{opt} .

If $M = 0.5$, $F_{\text{opt}} = 0.7$. If $M = 0.8$, $F_{\text{opt}} = 0.8$. For the beginning of 1976 the stock size was determined from an assumption that $F = 0.7$ for age groups 3 and older. For age groups 1 and 2, if $M = 0.65$, $F = 0.1$ and 0.2 , respectively. If $M = 0.8$, $F = 0.1$ and 0.3 , respectively.

In estimating of the stock size for 1977 the same values of F were used.

As a result it appeared that the stock size at age 2 and older would be 34.101×10^5 (408 thous. tons) in 1976, if $M = 0.5$.

If $M = 0.8$, the stock size in 1976 would number 61.403×10^5 (671 thous. tons), and in 1977 - 45.362×10^5 (575 thous.t.).

If $F = 0.7$ for 3 year old fish and older, and 0.2 and 0.3 for two year old fish, the catch in 1974 will be 124 thous.t., if $M = 0.5$, and 229 thous.t., if $M = 0.8$.

Therefore, for Subarea 4W and 4WW a silver hake catch within 125 thous. t. to 225 thous.t. can be recommended.
